A hybrid ytterbium-doped fiber–bulk laser source allowing the generation of 3 ps, 350 μ J, 116 MW peak power Fourier transform-limited pulses at 50 kHz repetition rate and 1030 nm wavelength is described. Pulse duration tunability is provided by an adjustable spectral compression-based seeder system. Energy scaling capabilities of the architecture by use of the divided-pulse amplification method are investigated. This source provides a robust, compact, and versatile solution for applications such as RF photocathode guns, x- and γ -ray generation by inverse Compton scattering, and optical parametric chirped-pulse amplification pumping.

High-repetition rate, high-energy picosecond sources are required for the development of secondary sources, such as photocathode RF guns, x- and γ -ray generation using inverse Compton scattering, and optical parametric chirped-pulse amplification (OPCPA) systems. These applications have noteworthy operating points in the 1–20 ps laser pulse duration regime, and often specify a narrow spectral bandwidth. For electron gun and OPCPA applications [1–3], the narrow spectral width is dictated by the need to use the second, third, or fourth harmonic of the laser initial frequency. Nonlinear frequency conversion is made considerably simpler if the initial pulses are close to Fourier transform-limited (FTL), relaxing constraints on the spectral acceptance of the process. X-ray sources using inverse Compton scattering use resonant cavity enhancement of the laser radiation, for which a narrower spectrum allows much larger field enhancement factors [4,5].

A widely adopted solution to amplify picosecond pulses relies on the use of Nd-doped materials, such as Nd:YVO₄. Such amplifiers benefit from a large achievable gain and moderate setup complexity [6–8]. By cascading several amplification stages or using multipass geometries, energies of several

hundreds of microjoules can be obtained in 10 ps pulses [9,10]. However, the narrow spectral emission cross section of neodymium does not allow the generation of pulse durations below 10 ps [10,11]. Moreover, average power scaling of these systems is limited by the relatively large quantum defect.

In contrast, systems based on ytterbium-doped materials allow average power scaling due to the low quantum defect of the pumping scheme, and broader spectral emission cross sections permit the generation of much shorter pulses, well in the femtosecond-picosecond regime [12,13]. For example, a system delivering 1.3 mJ, 7 ps pulses at 800 kHz repetition rate, corresponding to an average power beyond 1 kW, has been demonstrated [13], although in a relatively complex setup.

Ytterbium-doped fibers amplifiers (YDFAs) can also be used to amplify picosecond pulses, with the associated benefits of large gain, beam quality, and average power scaling, but the small core dimensions restrict the pulse energy below 100 μ J [14,15]. The chirped-pulse amplification technique (CPA) that is routinely used to scale the energy of femtosecond systems cannot be easily implemented for FTL picosecond pulses due to the narrow spectral bandwidth. However, an equivalent attractive alternative, denoted as divided-pulse amplification (DPA), has recently been used in this context [16,17], and in high-energy femtosecond fiber amplifiers [18].

In this Letter, we demonstrate a FTL picosecond source composed of a seeder system tunable in pulse duration and a hybrid fiber–bulk amplifier able to provide large gain, high pulse energy, and high average power. Pulse-width tunability is obtained by exploiting the spectral compression effect induced by self-phase modulation (SPM) in an optical fiber. The DPA architecture is used to scale the pulse energy beyond the self-focusing threshold both in the fiber amplifier and in the Yb:YAG bulk amplifier. This system has the advantage to be relatively simple compared to already existing sources used for the same applications [11,19]. This results in a source capable of delivering 3 ps, 350 μ J pulses at a repetition rate of 50 kHz, corresponding to 17.5 W average power. These performances are obtained in a compact and robust setup, and can be easily adjusted in the 3–20 ps range of pulse duration, in

energy (10–350 μ J), and in average power (10–50 W), making it a particularly versatile source.

The experimental setup, schematically shown in Fig. 1, consists of a front-end generating tunable-in-duration picosecond pulses followed by a fiber power amplifier and an Yb:YAG booster for the generation of energetic output pulses. The front-end is composed of an Yb:KYW bulk oscillator (Mikan, Amplitude Systemes) operating at 54 MHz repetition rate, and delivering 250 fs pulses centered at 1030 nm with 1.5 W average power. Pulses are then temporally stretched to picosecond durations using a 1750 l/mm grating-based arrangement introducing negative chirp. A fiber-based acousto-optic modulator is used to decrease the repetition rate of the oscillator before amplification in a core-pumped YDFA using a 6 μ m core and a 2 m long fiber. The repetition rate of the fiber amplifier is 4 MHz. When negatively chirped pulses are subjected to SPM in this amplifier, spectral components at both ends of the spectrum are redistributed toward the central wavelength, leading to a spectral narrowing of the pulses [20]. After a propagation length that depends on the initial chirp and strength of the nonlinearity, FTL pulses can be obtained. By controlling the input chirp of the pulse and gain of the amplifier, FTL pulses with continuously tunable pulse width in the range 3–30 ps are easily generated. Figure 2 shows the oscillator and picosecond pulse spectrum after spectral compression—for initial group delay dispersion of -0.48 ps² and -2.25 ps²—corresponding to a pulse duration of 3 ps and 20 ps, respectively. The obtained full width at half-maximum spectral bandwidths are 0.7 and 0.19 nm, respectively, confirming the quasi-FTL nature of these pulses. The typical pulse energy out of this first pulse-shaping amplifier stage is 5–30 nJ.

Fig. 2. (a) Initial oscillator spectrum (blue), compressed spectrum for 3 ps (red) and 20 ps (green) pulses. (b) Together with corresponding autocorrelation traces.

Since the generation of FTL picosecond pulses relies on a nonlinear process, a legitimate concern arises over the stability of the narrow spectrum. To investigate this aspect, a long-term measurement of the output spectrum is carried out in the configuration where the amount of SPM is the largest, corresponding to long pulse durations. Figure 3 displays the spectrum of 20 ps pulses and the average power at the output of the first YDFA stage recorded over 9 h, showing power fluctuations of 0.3% RMS and spectral width fluctuations of 3% RMS. The use of a highly stable bulk oscillator together with well-integrated fiber components allows this stability, and residual fluctuations are attributed to beam pointing fluctuations at the input of the fiber subsystem.

Further described experiments are carried out with 3 ps pulses. The first power amplifier is based on a 0.8 m long 85/265 μ m double-clad distributed-mode filtering rod-type ytterbium-doped fiber pumped with a 50 W fiber-coupled high-power pump diode system at 976 nm.

It is operated in a double-pass configuration. Despite the very large mode area of the fiber, SPM can induce spectral broadening in this stage depending on the output energy. A convenient way to mitigate this effect consists of partially distributing the spectral compression process in the power amplifier by adjusting the gain of the shaping stage. This allows a maximum pulse energy of 1.5 μ J for 3 ps pulses, corresponding to 500 kW peak power, while preserving FTL pulses at the output.

Further energy scaling of this stage is investigated based on the use of the DPA concept. This technique relies on the division of the input pulse into several less energetic temporal replicas [13]. After amplification, these replicas are combined to regenerate a single output pulse. The replicas for this power amplifier stage are generated with a set of three properly oriented yttrium vanadate crystals, which exhibit a large group delay birefringence of 0.7 ps/mm. The length of the smallest crystal is 10 mm corresponding to a differential group delay of 7 ps, twice the input pulse duration. The two other crystal lengths are 20 and 40 mm (by combining two 20 mm crystals), leading to the generation of eight pulse replicas. In each crystal, the incident polarization state is linear and oriented at 45° of the optical axes, generating at the output two temporally

Fig. 3. Long-term stability of the front-end for 20 ps pulse generation. Spectral shape at sampled times (right); average power stability of the oscillator (top).

separated sets of replicas of equal amplitude and orthogonal polarization. Passive recombination is achieved through a 90° polarization rotation (using a Faraday rotator), which ensures a complementary propagation path inside the birefringent crystals on the way back, and thus a complete compensation of the previously induced delays. Nonperfect recombination can originate in differential effects among replicas such as a phase shift or gain. In this case, part of the energy of the replicas is directed toward the orthogonal output polarization state, denoted as the uncombined output. Parasitic pulses in the time domain can also appear on the combined output.

Energy scaling results using DPA are shown in Fig. 4. At low energy per replica and for two replicas, the combining efficiency, defined as the combined power divided by total output power, is 99%. This efficiency decreases to 96% for eight temporal replicas, and we attribute this decrease to slight misalignment of crystal orientations in the dividing/combining stages. At the maximum energy of 1.5 μJ per replica, the efficiency decreases from 96% for two replicas down to 88% for eight replicas. This is attributed to the increased sensitivity of the system to nonperfect replica amplitude equalization that can be turned into phase discrepancies among replicas through accumulated SPM in the amplifier, as detailed in [21]. However, combined output energy of 9.3 μJ is achieved for 3 ps pulses, corresponding to 3 MW peak power, a record value for a quasi-FTL ps fiber amplifier [14,15,17]

To further scale the energy, an additional amplifier based on a 10 mm long Yb:YAG crystal is used. Because of the large gain provided by this bulk booster stage, the DPA divider/combiner is used at the input of the bulk booster. Indeed, the output energy provided by the power fiber amplifier with DPA—using one vanadate crystal—generating two replicas, approximately 3 μJ , is sufficient to ensure efficient energy extraction in the bulk booster, and DPA is needed at this stage to provide energy scaling capabilities. The DPA divider for the bulk Yb:YAG booster generates four replicas to accommodate higher peak power: the first temporal division is based on a combination of thin-film polarizer and free-space delay line (10 cm/330 ps), and the second division is based on a 20 mm long yttrium vanadate crystal (15 ps). This allows the final combining process to take place in free space, thereby avoiding self-focusing issues.

The input beam is focused inside the Yb:YAG crystal down to a 400 μm waist diameter. The crystal is pumped by a diode system emitting 170 W of average power at 969 nm, and coupled to a 200 μm , 0.22 NA pump fiber. The output facet of the pump fiber is imaged inside the crystal with a diameter of

500 μm . Heat removal in the crystal is operated by water cooling of the top and bottom facets of the crystal through a copper mount. The crystal is thermally contacted to the copper mount by a sheet of indium.

We first investigate the output power/energy of the bulk amplifier as a function of repetition rate at a maximum pump power of 170 W, as shown in Fig. 5. An additional acousto-optic modulator located between the rod-type amplifier and the bulk booster allows us to make this systematic study. The output pulse energy increases from 45 μJ at 1 MHz repetition rate to 350 μJ at 50 kHz, corresponding to average powers of 45 and 18 W, respectively. The 350 μJ energy corresponds to a peak power of 116 MW, and the Kerr focal length associated with this peak power is <1 cm in YAG. It is clear that severe self-focusing would occur without using the DPA system. With the DPA activated, the B-integral is estimated around 0.22 rad/replica. In order to decouple, identify, and compensate the thermal lens and the Kerr lens, the setup is aligned in two steps. First, we operate at full pump power but low seed energy to observe the thermal lens only. The backreflecting mirror position is then optimized to compensate it. Afterward, nonlinear effects can be observed by increasing the input signal. The beam propagation changes imparted by the Kerr lens during first and second passes and is more difficult to fully compensate.

The combined power, uncombined power, and combining efficiency are plotted as a function of pump power at 50 kHz repetition rate in Fig. 6. The DPA combining efficiency of the Yb:YAG booster is above 97% in all cases, because of the low value of B-integral estimated to be 0.3 rad per replica (350 μJ output pulse energy). It is also worth noticing that all depolarization effects are also low since they are included in the 3% combination losses. This illustrates the relevance of DPA for bulk amplifiers pumped with high-brightness diodes, allowing energy-scaling beyond single-pulse self-focusing and optical damage limitations. No noticeable evolution is observed between input and output spectra of the booster amplifier, as shown in Fig. 5. Indeed, spectral evolution essentially occurs during spectral compression, which takes place in the fiber system. The amplified spontaneous emission (ASE) appears to be negligible, as shown in Fig. 5 representing the amplified spectrum in log-scale.

Finally, we investigate spatial properties of the output pulses at 50 kHz repetition rate and maximum energy of 350 μJ . The spatial quality is also pristine, with M^2 values below 1.15 in both directions and a Gaussian beam profile. For a higher repetition rate, above 40 W output power, spatial distortions start

to appear due to additional heat load induced by strong pump absorption and high gain saturation. The thermal lens limitation is not related to its dioptric power value but to aberrations that cause beam profile degradation.

We also investigated the energy extraction with 20 ps pulses (see Fig. 7). Thanks to the reduced peak intensity we were able to extract 720 μJ from the Yb:YAG booster without implementing DPA. Damage threshold was reached slightly above 860 μJ for a single pulse corresponding to a fluence around 500 mJ/cm^2 . The use of DPA allows us to operate significantly below the damage threshold.

In conclusion, we report a hybrid high-power versatile source of FTL picosecond pulses based on a rod-type fiber amplifier followed by a bulk Yb:YAG booster. Energy scaling using the DPA technique for the fiber amplifier allows obtaining record performances for this type of system. This method is also advantageously used to scale the energy of the bulk booster, allowing the generation of 350 μJ , 3 ps pulses for a peak power of 116 MW. Higher energy has been reached up to 720 μJ with 20 ps pulse duration for a peak power of 36 MW without any divided pulse scheme. We believe that this type of versatile

architecture will allow further energy scaling to the millijoule level mostly by adding division stages, since 32 replica systems have already been demonstrated [16]. It is worth noticing that with such a hybrid configuration based on a fiber-bulk amplifier, we measured in hybrid industrialized systems power fluctuation of 0.3% rms and beam pointing stability of 30 μrad RMS over 15 h. The bulk booster allows simple energy scaling of over an order of magnitude at the output of a CPA free picosecond fiber system [11] while preserving a very clean and narrow spectrum compatible with highly efficiency frequency conversion.
